Dynamic hedging of synthetic CDO tranches

Areski Cousin
ISFA, Université Lyon 1

Séminaire Lyon–Lausanne

Lausanne, 19 March 2010
In this presentation, we address the hedging issue of CDO tranches in a market model where pricing is connected to the cost of the hedge.

In credit risk market, models that connect pricing to the cost of the hedge have been studied quite lately.

Discrepancies with the interest rate or the equity derivative market.

Model to be presented is not new, require some stringent assumptions, but the hedging can be fully described in a dynamical way.
Presentation related to the papers:

- *Hedging default risks of CDOs in Markovian contagion models* (2008), to appear in Quantitative Finance, with Jean-Paul Laurent and Jean-David Fermanian

- *Hedging CDO tranches in a Markovian environment* (2009), book chapter with Monique Jeanblanc and Jean-Paul Laurent

- *Hedging portfolio loss derivatives with CDSs* (2010), working paper with Monique Jeanblanc

- *Delta-hedging correlation risk?* (2010), working paper with Rama Cont, Stéphane Crépey and Yu Hang Kan

- *Dynamic hedging of synthetic CDO tranches: Bridging the gap between theory and practice* (2010), book chapter with Jean-Paul Laurent
Contents

1 Theoretical framework

2 Homogeneous Markovian contagion model

3 Empirical results
Default times

- $n$ credit references
- $\tau_1, \ldots, \tau_n$ : default times defined on a probability space $(\Omega, \mathcal{G}, \mathbb{P})$
- $N^i_t = 1\{\tau_i \leq t\}$, $i = 1, \ldots, n$ : default indicator processes
- $\mathcal{H}^i = (\mathcal{H}^i_t)_{t \geq 0}$, $\mathcal{H}^i_t = \sigma(N^i_s, s \leq t)$, $i = 1, \ldots, n$ : natural filtration of $N^i$
- $\mathcal{H} = \mathcal{H}^1 \vee \cdots \vee \mathcal{H}^n$ : global filtration of default times

Dynamic hedging of synthetic CDO tranches
Default times

- No simultaneous defaults: \( \mathbb{P}(\tau_i = \tau_j) = 0, \forall i \neq j \)
- Default times admit \( \mathbb{H} \)-adapted default intensities
  - For any \( i = 1, \ldots, n \), there exists a non-negative \( \mathbb{H} \)-adapted process \( \alpha^i,\mathbb{P} \) such that
    \[
    M^{i,\mathbb{P}}_t := N^i_t - \int_0^t \alpha^{i,\mathbb{P}}_s ds
    \]
    is a \( (\mathbb{P}, \mathbb{H}) \)-martingale.
  - \( \alpha^i,\mathbb{P}_t = 0 \) on the set \( \{t > \tau_i\} \)
  - \( M^{i,\mathbb{P}}, i = 1, \ldots, n \) will be referred to as the fundamental martingales
**Market Assumption**

- **Instantaneous digital CDS** are traded on the names $i = 1, \ldots, n$.

- **Instantaneous digital CDS** on name $i$ at time $t$ is a stylized bilateral agreement:
  - Offer credit protection on name $i$ over the short period $[t, t + dt]$.
  - Buyer of protection receives 1 monetary unit at default of name $i$.
  - In exchange for a fee equal to $\alpha^i_t dt$.

\[
\begin{align*}
0 & \quad 1 - \alpha^i_t dt : \text{default of } i \text{ between } t \text{ and } t + dt \\
& \\n& \quad -\alpha^i_t dt : \text{survival of name } i \\
t & \quad t + dt
\end{align*}
\]

- Cash-flow at time $t + dt$ (buy protection position): $dN^i_t - \alpha^i_t dt$.
- $\alpha^i_t = 0$ on the set $\{t > \tau_i\}$ (Contract is worthless).
Market Assumption

- Credit spreads are driven by defaults: \(\alpha^1, \ldots, \alpha^n\) are \(\mathbb{H}\)-adapted processes.
- Payoff of a self-financed strategy

\[
V_0 e^{rT} + \sum_{i=1}^{n} \int_0^T \delta^i e^{r(T-s)} \left( dN^i_s - \alpha^i_s ds \right).
\]

- \(r\): default-free interest rate
- \(V_0\): initial investment
- \(\delta^i, i = 1, \ldots, n\), \(\mathbb{H}\)-predictable process

CDS cash-flow
Theoretical framework
Homogeneous Markovian contagion model
Empirical results

Hedging and martingale representation theorem

**Theorem (Predictable representation theorem)**

Let $A \in \mathcal{H}_T$ be a $\mathbb{P}$-integrable random variable. Then, there exists $\mathbb{H}$-predictable processes $\theta^i, i = 1, \ldots, n$ such that

$$
A = \mathbb{E}[A] + \sum_{i=1}^{n} \int_{0}^{T} \theta^i_s \left( dN^i_s - \alpha^i_s, \mathbb{P} ds \right) 
$$

$$
= \mathbb{E}[A] + \sum_{i=1}^{n} \int_{0}^{T} \theta^i_s dM^i_s, \mathbb{P}
$$

and $\mathbb{E} \left( \int_{0}^{T} |\theta^i_s| \alpha^i_s, \mathbb{P} ds \right) < \infty$. 

Dynamic hedging of synthetic CDO tranches
Hedging and martingale representation theorem

Theorem (Predictable representation theorem)

Let \( A \in \mathcal{H}_T \) be a \( \mathbb{Q} \)-integrable random variable. Then, there exists \( \mathbb{H} \)-predictable processes \( \hat{\theta}^i \), \( i = 1, \ldots, n \) such that

\[
A = \mathbb{E}_\mathbb{Q}[A] + \sum_{i=1}^{n} \int_0^T \hat{\theta}^i_s \left( dN^i_s - \alpha^i_s \, ds \right) \quad \text{(CDS cash-flow)}
\]

\[
= \mathbb{E}_\mathbb{Q}[A] + \sum_{i=1}^{n} \int_0^T \hat{\theta}^i_s \, dM^i_s
\]

and \( \mathbb{E}_\mathbb{Q} \left( \int_0^T |\theta^i_s| \alpha^i_s \, ds \right) < \infty \).
Building a change of probability measure

- Describe what happens to default intensities when the original probability is changed to an equivalent one.

- From the PRT, any Radon-Nikodym density \( \zeta \) (strictly positive \((\mathbb{P}, \mathbb{H})\)-martingale with expectation equal to 1) can be written as

\[
d\zeta_t = \zeta_t \sum_{i=1}^{n} \pi^i_t dM^i_t, \quad \zeta_0 = 1
\]

where \( \pi^i, i = 1, \ldots, n \) are \( \mathbb{H} \)-predictable processes.
Conversely, the (unique) solution of the latter SDE is a local martingale (Doléans-Dade exponential)

\[ \zeta_t = \exp \left( - \sum_{i=1}^{n} \int_{0}^{t} \pi_s \alpha_s^{i,P} \, ds \right) \prod_{i=1}^{n} (1 + \pi_{\tau_i}^i)^{N_t^i} \]

- The process \( \zeta \) is non-negative if \( \pi^i > -1 \), for \( i = 1, \ldots, n \)
- The process \( \zeta \) is a true martingale if \( \mathbb{E}_{P} [\zeta_t] = 1 \) for any \( t \) or if \( \pi^i \) is bounded, for \( i = 1, \ldots, n \)
Theorem (Change of probability measure)

Define the probability measure $Q$ as

$$dQ|\mathcal{H}_t = \zeta_t dP|\mathcal{H}_t.$$ 

where

$$\zeta_t = \exp \left( - \sum_{i=1}^{n} \int_{0}^{t} \pi_{s} \alpha_{s}^{i, P} ds \right) \prod_{i=1}^{n} (1 + \pi_{\tau_i}^{i}) N_{t}^{i}$$

Then, for any $i = 1, \ldots, n$, the process

$$M_{t}^{i} := M_{t}^{i, P} - \int_{0}^{t} \pi_{s} \alpha_{s}^{i, P} ds = N_{t}^{i} - \int_{0}^{t} (1 + \pi_{s}^{i}) \alpha_{s}^{i, P} ds$$

is a $Q$-martingale. In particular, the $(Q, \mathbb{H})$-intensity of $\tau_i$ is $(1 + \pi_{\tau_i}^{i}) \alpha_{\tau_i}^{i, P}$. 

Dynamic hedging of synthetic CDO tranches
Hedging and martingale representation theorem

- From the absence of arbitrage opportunity
  \[ \{ \alpha_t^i > 0 \} \stackrel{\mathbb{P}-a.s.}{=} \{ \alpha_t^{i,\mathbb{P}} > 0 \} \]

- For any \( i = 1, \ldots, n \), the process \( \hat{\pi}^i \) defined by:
  \[
  \hat{\pi}^i_t = \left( \frac{\alpha_t^i}{\alpha_t^{i,\mathbb{P}}} - 1 \right) \left( 1 - N_t^i \right)
  \]
  is an \( \mathbb{H} \)-predictable process such that \( \hat{\pi}^i > -1 \)

- The process \( \zeta \) defined with \( \pi^1 = \hat{\pi}^1, \ldots, \pi^n = \hat{\pi}^n \) is an admissible Radon-Nikodym density

- Under \( \mathbb{Q} \), credit spreads \( \alpha^1, \ldots, \alpha^n \) are exactly the intensities of default times
The theoretical framework
Homogeneous Markovian contagion model
Empirical results

Hedging and martingale representation theorem

- The predictable representation theorem also holds under $Q$
- In particular, if $A$ is an $\mathcal{H}_T$ measurable payoff, then there exists $\mathbb{H}$-predictable processes $\hat{\theta}^i_i, i = 1, \ldots, n$ such that

$$A = \mathbb{E}_Q [A | \mathcal{H}_t] + \sum_{i=1}^{n} \int_{t}^{T} \hat{\theta}^i_i (dN^i_s - \alpha^i_s ds).$$

- Starting from $t$ the claim $A$ can be replicated using the self-financed strategy with
  - the initial investment $V_t = \mathbb{E}_Q [e^{-r(T-t)} A | \mathcal{H}_t]$ in the savings account
  - the holding of $\delta^i_s = \hat{\theta}^i_i e^{-r(T-s)}$ for $t \leq s \leq T$ and $i = 1, \ldots, n$ in the instantaneous CDS
- As there is no charge to enter a CDS, the replication price of $A$ at time $t$ is $V_t = \mathbb{E}_Q [e^{-r(T-t)} A | \mathcal{H}_t]$
A depends on the default indicators of the names up to time $T$

- includes the cash-flows of CDO tranches or basket credit default swaps, given deterministic recovery rates

The latter theoretical framework can be extended to the case where actually traded CDS are considered as hedging instruments

- See Cousin and Jeanblanc (2010) for an example with a portfolio composed of 2 names or in a general $n$-dimensional setting when default times are assumed to be ordered
Hedging and martingale representation theorem

- **Risk-neutral measure** can be explicitly constructed
  - We exhibit a continuous change of probability measure

- **Completeness of the credit market** stems from a martingale representation theorem
  - Perfect replication of claims which depend only upon the default history with CDS on underlying names and default-free asset
  - Provide the replication price at time $t$

- But does not provide any operational way of constructing hedging strategies

- **Markovian assumption** is required to effectively compute hedging strategies
The theoretical framework
Homogeneous Markovian contagion model
Empirical results

Markovian contagion model

- Pre-default intensities only depend on the **current status of defaults**

\[ \alpha^i_t = \tilde{\alpha}^i (t, N_t^1, \ldots, N_t^n) 1_{t<\tau_i}, \ i = 1, \ldots, n \]

- **Ex:** Herbertsson - Rootzén (2006)

\[ \tilde{\alpha}^i (t, N_t^1, \ldots, N_t^n) = a_i + \sum_{j \neq i} b_{i,j} N_t^j \]

- **Ex:** Lopatin (2008)

\[ \tilde{\alpha}^i (t, N_t) = a_i(t) + b_i(t)f(t, N_t) \]

- **Connection with continuous-time Markov chains**
  - \((N_t^1, \ldots, N_t^n)\) Markov chain with possibly \(2^n\) states
  - Default times follow a **multivariate phase-type distribution**

Dynamic hedging of synthetic CDO tranches
Pre-default intensities only depend on the current number of defaults.

All names have the same pre-default intensities

\[ \alpha^i_t = \tilde{\alpha}(t, N_t) \, 1_{t \leq \tau_i}, \quad i = 1, \ldots, n \]

where

\[ N_t = \sum_{i=1}^{n} N^i_t \]

This model is also referred to as the local intensity model.
Homogeneous Markovian contagion model

- No simultaneous default, the intensity of $N_t$ is equal to

$$\lambda(t, N_t) = (n - N_t)\tilde{\alpha}(t, N_t)$$

- $N_t$ is a continuous-time Markov chain (pure birth process) with generator matrix:

$$\Lambda(t) = \begin{pmatrix}
-\lambda(t, 0) & \lambda(t, 0) & 0 & 0 \\
0 & -\lambda(t, 1) & \lambda(t, 1) & 0 \\
0 & \ddots & \ddots & \ddots \\
0 & 0 & -\lambda(t, n - 1) & \lambda(t, n - 1) \\
0 & 0 & 0 & 0 & 0
\end{pmatrix}$$

- Model involves as many parameters as the number of names
Replication price of a European type payoff

\[ V(t, k) = \mathbb{E}_Q \left[ e^{-r(T-t)} \Phi(N_T) \mid N_t = k \right] \]

- \( V(t, k), k = 0, \ldots, n - 1 \) solve the backward Kolmogorov differential equations:

\[ \frac{\delta V(t, k)}{\delta t} = r V(t, k) - \lambda(t, k) (V(t, k + 1) - V(t, k)) \]

Computation of credit deltas

- \( V(t, N_t) \), price of a CDO tranche (European type payoff)
- \( V^I(t, N_t) \), price of the CDS index (European type payoff)

\[
V(t, N_t) = \mathbb{E}^Q \left[ e^{-r(T-t)} \Phi(N_T) \ | \ N_t \right]
\]

\[
V^I(t, N_t) = \mathbb{E}^Q \left[ e^{-r(T-t)} \Phi^I(N_T) \ | \ N_t \right]
\]

- Using standard Itô’s calculus

\[
dV(t, N_t) = \left( V(t, N_t) - \delta^I(t, N_t) V^I(t, N_t) \right) r dt + \delta^I(t, N_t) dV^I(t, N_t)
\]

where

\[
\delta^I(t, N_t) = \frac{V(t, N_t + 1) - V(t, N_t)}{V^I(t, N_t + 1) - V^I(t, N_t)}.
\]

- Perfect replication with the index and the risk-free asset
Pricing and hedging in a binomial tree

- **Binomial tree**: discrete version of the homogeneous contagion model

\[
\Lambda(t) = \begin{pmatrix}
-\lambda(t,0) & \lambda(t,0) & 0 & 0 \\
0 & -\lambda(t,1) & \lambda(t,1) & 0 \\
0 & 0 & \ddots & \ddots \\
0 & 0 & 0 & -\lambda(t,n-1) & \lambda(t,n-1)
\end{pmatrix}
\]

- Given some loss intensities \( \lambda(t,k) \), CDO tranches and index price computed by **backward induction**:

\[
V(t+2,k+2) \\
V^I(t+2,k+2) \\
V(t+1,k+1) \\
V^I(t+1,k+1) \\
V(t+2,k+1) \\
V^I(t+2,k+1) \\
V(t+1,k) \\
V^I(t+1,k) \\
V(t+2,k) \\
V^I(t+2,k)
\]
Empirical results

- Slice the credit portfolio into different risk levels or **CDO tranches**
- **ex:** CDO tranche on **standardized Index** such as **CDX North America Investment Grade**

Empirical results

Two different calibration methods used to fit loss intensities

- **Parametric method**: \( \lambda(t, k) = \lambda(k) = (n - k) \sum_{i=0}^{k} b_i \) (Herbertsson (2008))
- **Entropy Minimisation algorithm calibration**: 
  \[ \inf_{Q \in \Lambda} \mathbb{E}^Q_0 \left[ \frac{dQ}{dQ_0} \ln \left( \frac{dQ}{dQ_0} \right) \right] \]
  subject to the calibration constraints (Cont and Minca (2008))

\[ \text{Left : Cont, Cousin, Crépey and Kan (2010), Right : Cont and Minca (2008)} \]

Comparison of three alternative hedging methods

- **Gauss delta**: index spread sensitivity computed in a one-factor Gaussian copula model
  \[
  \Delta_{t}^{\text{Gauss}} = \frac{V(t, S_{t} + \varepsilon, \rho_{t}) - V(t, S_{t}, \rho_{t})}{V^{I}(t, S_{t} + \varepsilon) - V^{I}(t, S_{t})}
  \]
  where $V$ and $V^{I}$ are the Gaussian copula pricing function associated with (resp.) the tranche and the CDS index.

- **Local intensity delta**:
  \[
  \delta^{I}(t, N_{t}) = \frac{V(t, N_{t} + 1) - V(t, N_{t})}{V^{I}(t, N_{t} + 1) - V^{I}(t, N_{t})}.
  \]
  with both Parametric (Param) and Entropy Minimisation (EM) calibration methods

Conclusion:

- Hedging based on local intensity model with Entropy Minimisation calibration gives poor performance.
- No clear evidence to distinguish the performance based on the Gaussian copula model and the parametric local intensity model.
